Abstract

In the fabrication of high-speed Ti:LiNbO₃ optical waveguide modulators, the sputtering deposition of 1 μ m-thick-order SiO₂ films on LiNbO₃ substrates and the subsequent O₂ atmosphere annealing are key processes. However, large numbers of pinholes appear in the films after the annealing process limiting the fabrication yield. Here, we demonstrate that such pinholes are eliminated in films deposited on heated LiNbO₃ substrates. In addition to the common effect of increased film adhesive strength and density, the reduction in H₂O impurities in LiNbO₃ and SiO₂ by substrate heating is considered to be the reason for this phenomenon. © 1998 Elsevier Science S.A. 1. Introduction

Recent research on oxide materials is mainly focused on the synthesis of exotic, function-harmonized materials, such as perovskite based ferroelectric, ferromagnetic, and superconducting crystals [1-3]. However, in order to apply these attractive oxides to practical devices, we must first conduct an investigation into device fabrication technology. Actually, various kinds of oxide-based devices have been made. But the fabrication processes for these devices are used without regard to certain problems caused by oxide crystals [4,5].

LiNbO₃ is one of such promising materials, especially for integrated optical waveguide components. In fact, LiNbO₃-based optical modulators have already been installed in world-wide optical fiber communication systems [6]. However, while present LiNbO₃ modulator devices are produced via conventional photolithography, thin film deposition and dry etching technologies, many technical problems characteristic to the LiNbO₃ process, have been found. For instance, during the fluorocarbon plasma etching of a LiNbO₃ surface, LiF-based particles were found to precipitate and cause mechanical failure in the devices as

previously reported by Nagata et al. [7,8]. In this paper, the Problem appearing during the SiO₂ film formation process is analyzed, because the SiO₂ buffer layer is an important element in the development of high-speed LiNbO₃ optical modulators. The main problem of focus was the generation of pinholes in films after high temperature annealing which followed the sputtering process.

2. pinhole generation in SiO₂ films on LiNbO₃

On LiNbO₃ single crystal wafers, which include optical waveguides formed by thermal diffusion of Ti, SiO₂ buffer layers are deposited by either a vacuum evaporation method or an rf-magnetron sputtering method. However, with the increasing demand for high-speed operation at over 20Gb/s, a dense SiO₂ buffer layer deposited via the sputtering method is preferable because it can achieve a highly effective electro-optic interaction between the electrodes and the waveguides. Furthermore, a film thickness of over 1 μ m is needed to obtain a suitable electrical impedance matching, etc. between the Au electrodes and the LiNbO₃ substrate.

We found that during such dense and thick SiO₂ film deposition on LiNbO₃ substrates, the inevitably high internal film stress induced mechanical failures . such as large substrate deflections and broken substrates. In addition to

such general phenomena independent of the substrates, many pinholes were frequently observed in sputtering deposited SiO₂ films on LiNbO₃ after post-annealing. Furthermore, there was a tendency in the number of pinholes to increase significantly for thicker films (approx. 1 μm). In the actual device fabrication process, the deposition and post-annealing of thinner films has to be repeated a few times to suppress the development of pinholes. However, in order to improve the device fabrication yield, we explored possible reasons for the generation of pinholes and developed a method to completely eradicate them.

Fig. 1 shows a secondary electron microscopic (SEM) image of the typical pinholes that appeared in a 0.7 μm-

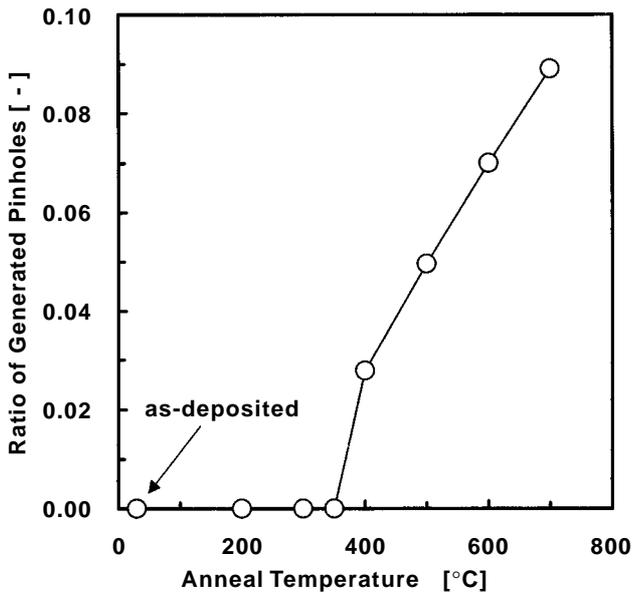

Fig. 2. The presence of pinholes, denoted by a ratio of the total width of pinholes measured to the total length of the surface measured, relative to annealing temperature.

thick SiO₂ film on a 3 inch diameter z-cut LiNbO₃ wafer after post-annealing at 600°C for 5 h in flowing O₂. Circular pinholes with 10-100 μm diameters were observed throughout the annealed wafer surface, while no pinhole was observed before annealing. The step height of the pinholes, measured by a stylus method, was the same as the thickness of the deposited film. Furthermore, an Auger electron spectroscopy (AES) was carried out on the bottom surface of the pinholes and no specific contaminant element was detected except for Nb from the LiNbO₃ and C with the same amount of that from the SiO₂ surface. These results, at the very least, indicate that the SiO₂ film was removed from the LiNbO₃ surface by the annealing and generated many pinholes.

In order to understand what influence the post-annealing temperature has on pinhole generation, a 1.2 μm thick SiO₂ film was deposited on a LiNbO₃ wafer and cut into 10 × 10 mm pieces, and then annealed under various heating conditions. The film was prepared by conventional rf-magnetron sputtering using the SiO₂ target and Ar/O₂ (=5/1 and approx. 0.4 Pa) mixture without intentional substrate heating. The deposition rate was 0.17-0.18nm/s. The deposited film was smooth without any pinholes even after the wafer cutting process. Before and after annealing, the surface morphology and optical refractive index of the film were examined.

Fig. 2 shows a change in the prevalence of pinholes, depending on the annealing temperature. As an index for the amount of pinholes, a 5 × 5 mm area of the samples was scanned by a stylus profilometer with a 0.5-mm interval between each scan, and the ratio of the total length of the pinhole bottoms (LiNbO₃ surface) measured to the total scan length (sum of lengths for the remaining film surface and the pinhole bottom) was calculated and plotted on the vertical axis of Fig. 2. In the experiments, the heating rate to

a certain annealing temperature and the holding time were fixed at 5 K/min and 5 h, respectively, while O_2 was introduced into the furnace at a rate of $500\text{cm}^3/\text{min}$. The cooling was done by simply turning off the heater. As shown, the generation of pinholes occurred at annealing temperatures beyond 350°C and became more frequent with increased temperature. With respect to annealing at 400°C , in order to determine the effect of heating rate, we attempted to heat at both a slower rate of 1 K/min and at a sudden shift to 400°C after 5 h of annealing at 300°C . These methods produced similar results. We thus concluded that the generation of pinholes was mainly affected by the annealing temperature itself.

Annealing below 350°C was the most effective method to prevent (mitigate) the formation of pinholes, but annealing at 600°C was necessary to obtain a steadily oxidized SiO_2 buffer layer. Fig. 3 reveals the change in the optical refractive index of the SiO_2 films depending on the annealing temperature. The refractive index was measured using a prism-coupler at an optical wavelength of 633nm . The refractive index of the as-deposited SiO_2 films decreased by oxygen atmosphere annealing mainly due to the increase in the level of oxygen in the film. For the present films, as shown in Fig. 3, the refractive index decreased at temperatures beyond 350°C and reached a minimum at temperatures between 500 and 600°C . At 700°C , the refractive index increased again, possibly due to a chemical interaction between LiNbO_3 and SiO_2 , such as a diffusion of Li. The results supported the theory that O_2 annealing at 500 – 600°C was the process necessary to obtain steadily oxidized SiO_2 films, although such high temperature annealing caused the formation of pinholes in films.

3. Elimination of pinholes by substrate heating

Thermal decomposition and evaporation of the contamination in the constituent materials was considered to be the reason for the generation of pinholes. In Fig. 1, few hill-like defects having sizes corresponding to pinholes, were observed, and they were considered to be caused by a generation of gases at the film/substrate boundary. The decomposition of organic contamination existing on the LiNbO_3 surface and the evaporation of molecular contamination in the LiNbO_3 were assumed to be possible origins of the gases.

At first, the effect of cleaning the surface of the LiNbO_3 wafer before the SiO_2 film deposition process was investigated. Some wet cleaning methods were used, but no difference was observed in the pinhole generation behavior.

Fig. 4. TDS profiles of SiO_2 films on LiNbO_3 for (a) change of the total pressure due to thermal decomposition of the sample, (b) evaporation of fragment 18 (H_2O), (c) fragment 28 (possibly due to organic contaminants), (d) fragment 32 (possibly due to O_2 and organic contaminants) and (e) fragment 40 (Ar).

These methods included ultrasonic cleaning in a commercial detergent or an acetone/ethyl alcohol mixture, and the amount of organic contamination was measured to decrease to 30-60 pg/cm² (mainly benzene and phthalic acid) from 4000 pg/cm² before cleaning. Here, the level of contamination was measured by gas chromatography accompanied with mass spectroscopy (GC/MS) of the thermally decomposed fragments of the surface contamination at 400°C. On the other hand, a dry etching cleaning of the surface by oxygen plasma was also attempted just before the film deposition in the same process chamber. This method, too, caused no notable reduction in the number of pinholes.

Then, in order to check the contaminant fragments actually evaporating from the SiO₂ films on the LiNbO₃, a thermal decomposition spectroscopy (TDS) analysis was carried out for the 1.2 μm-thick SiO₂ films prepared similarly to the samples shown in Figs. 2 and 3. Films were deposited on both sides of the LiNbO₃ to exclude the fragments directly evaporated from the LiNbO₃ from our measurements. In the measurements, a 6 × 6 mm square sample was heated in a vacuum (6 × 10⁻⁷ Pa) up to 1000°C at 60 K/min, while windows of the mass detector were set at 17, 18, 20, 28, 32, and 40. Fragments having mass number 17 and 18 were considered to come mainly from H₂O, fragments 20 and 40 were from Ar, fragment 28 was from CO, N₂, C₂H₄, etc. and fragment 32 was from O₂, CH₃O, etc. Fig. 4 shows the TDS profiles for (a) a change of the total pressure due to thermal decomposition of the

sample, (b) evaporation of the fragment 18 (H₂O), (c) fragment 28 (possibly due to organic contaminants), (d) the fragment 32 (possibly due to O₂ and organic contaminants), and (e) the fragment 40 (Ar). As can be seen, the dominant fragment evaporated from the SiO₂ on LiNbO₃ was identified as H₂O (see Fig. 4b), and no fragment due possibly to organic contamination was found below 800°C. Furthermore, the evaporation of H₂O began at about 300°C and saturated at 700-800°C. This behavior seemed to correspond with changes in the amount of pinholes (Fig. 2) and the refractive index (Fig. 3). Therefore, we considered that the thermal decomposition and the evaporation of H₂O impurities in the materials were plausible origins of pinholes.

In order to track the possible origin of the H₂O, a z-cut LiNbO₃ sample was similarly investigated by TDS. Fig. 5 shows the TDS profiles for fragments 2 (H₂) and 18 (H₂O), respectively. The LiNbO₃ crystal could have H₂O impurities as the H on Li sites and as the OH in O-O planes normal to the z-axis. The results suggest that the LiNbO₃ wafer itself could become the source of H₂O at elevated temperatures.

From the above experimental results, we surmised that substrate heating during the SiO₂ deposition could be effective in reducing H₂O impurities both in the LiNbO₃ substrates and the growing films. Fig. 6 shows the relationship between substrate temperatures during approx. 1.2 μm thick film depositions and amounts of pinholes that appear after post-annealing at 600°C for 5 h. By the 200°C deposition, the generation of pinholes could be significantly reduced and almost completely eliminated by the 250°C

deposition. Considering the results of Fig. 5, the H₂O impurity in the LiNbO₃ could be partially removed by heating at 200-250°C beforehand to prevent (mitigate) H₂O evaporation at the film/LiNbO₃ boundary during post-annealing.

Similar depositions at 250°C and post-annealing was carried out more than five times using 3-inch diameter LiNbO₃ wafers, and no pinholes have been detected yet by optical microscopic observation. The refractive indices at 633nm wavelength for these SiO₂ films were measured to be 1.468 before post-annealing and 1.462 after annealing. On the other hand, the film deposited without substrate heating showed a refractive index of 1.460 after annealing (see Fig. 3), suggesting that the film density was also improved by substrate heating.

4. Conclusion

The generation of pinholes in sputtering deposited SiO₂ films on LiNbO₃ after post-annealing at 400-700°C could be successfully suppressed by carrying out the deposition at elevated temperatures, preferably beyond 250°C. The results can be effectively applied to the fabrication of high-speed Ti:LiNbO₃ optical waveguide modulators, especially those over 20 Gb/s, because the sputtering deposition of 1-1.5 μm SiO₂ films on LiNbO₃ substrates and the O₂ atmosphere annealing that follows are key processes to

satisfy the design demand on constituent materials for these devices. From our impurity analysis results, we concluded that the reason for the elimination of pinholes was reduction of H₂O impurities in LiNbO₃ and SiO₂ by substrate heating, in addition to common effect of increased film adhesive strength and density.
